

# Algorithms, Evidence, and Data Science Cookbook

## Part I: Classic Statistical Inference

- \* **Population:** the entire group
- \* **Sample:** a subset of the population
- \* **Mean:**  $\mu$  is the mean of the population;  $\bar{x}$  is the mean of the sample

$$\frac{1}{n} \sum_{i=1}^n x_i$$

- \* **Variance:** the dispersion around the mean

Variance of a population:      Variance of a sample:

$$\sigma^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \mu)^2 \quad s^2 = \frac{1}{n} \sum_{i=1}^n (x_i - \bar{x})^2$$

- \* **Standard Deviation:** square root of the variance
- \* **Standard Error:** an estimate of the standard deviation of the sampling distribution

For a mean:

$$se(\bar{x}) = \sqrt{\frac{s^2}{n}}$$

For the difference between two means:

$$se(\bar{x}_1, \bar{x}_2) = \sqrt{\frac{s_1^2}{n_1} + \frac{s_2^2}{n_2}}$$

## Algorithms and Inference

- \* **Algorithm:** set of data probability-steps to produce an estimator
- \* **Inference:** measuring the uncertainty around the estimator *e.g.*:  $\bar{x}$  the algorithm, while  $se(\bar{x})$  is the inference

## A Regression Example

### Linear Regression

any regression is a conditional mean  $\hat{Y}_i = E(Y_i | X_i)$

- \*  $Y$  : response variable
- \*  $X$  : covariate/predictor/feature
- \*  $\hat{\beta}_0, \hat{\beta}_1$  : regression coefficients

$$\hat{\beta}_0 = \hat{Y} - \hat{\beta}_1 \hat{X} \quad \hat{\beta}_1 = \frac{\sum_{i=1}^n (X_i - \bar{X})(Y_i - \bar{Y})}{\sum_{i=1}^n (X_i - \bar{X})^2}$$

$$se(\hat{\beta}_0) = \hat{\sigma}^2 \left[ \frac{1}{n} + \frac{\bar{x}^2}{\sum_{i=1}^n (X_i - \bar{X})^2} \right] \quad se(\hat{\beta}_1) = \frac{\hat{\sigma}^2}{\sum_{i=1}^n (X_i - \bar{X})^2}$$

- \* predicted values = fitted curve given  $x$ :

$$\hat{Y}(x) = \hat{\beta}_0 + \hat{\beta}_1 x$$

- \* residuals  $\hat{\epsilon}$ :

$$\hat{\epsilon}_i = Y_i - \hat{Y}_i = Y_i - \hat{\beta}_0 + \hat{\beta}_1 X_i$$

- \* residual sum of squares  $RSS$

$$RSS(\hat{\beta}_0, \hat{\beta}_1) = \sum_{i=1}^n \hat{\epsilon}_i^2$$

- \* mean square error  $\hat{\sigma}^2$

$$\hat{\sigma}^2 = \frac{RSS(\hat{\beta}_0, \hat{\beta}_1)}{n - 2}$$

## LOWESS & LOESS

- \* 1) specify the number of points within the range/window  $n$
- \* 2) neighbour weightings  $w(x_k)$

$$w(x_k) = \left( 1 - \left| \frac{x_i - x_k}{d} \right|^3 \right)^3 \quad \begin{array}{l} \text{for } k = 1, \dots, n \\ d \text{ is the distance between } x_i \\ \text{and the } k^{th} \text{ neighbouring point} \end{array}$$

- \* 3) for each range, estimate a regression function

LOWESS:  $\hat{y}_k = a + bx_k$

LOESS:  $\hat{y}_k = a + bx_k + cx_k^2$

- \* 4) robust weightings  $G(x_k)$

$$G(x_k) = \begin{cases} \left( 1 - \left( \frac{|y_i - \hat{y}_i|}{6 \text{median}(|y_i - \hat{y}_i|)} \right)^2 \right)^2, & \left| \frac{|y_i - \hat{y}_i|}{6 \text{median}(|y_i - \hat{y}_i|)} \right| < 1 \\ 0, & \left| \frac{|y_i - \hat{y}_i|}{6 \text{median}(|y_i - \hat{y}_i|)} \right| \geq 1 \end{cases}$$

LOWESS:  $\hat{y}_k = \sum_k w(x_k) G(x_k) (a + bx_k)^2$

LOESS:  $\hat{y}_k = \sum_k w(x_k) G(x_k) (a + bx_k + cx_k^2)^2$

- \* 5) A series of new smoothed values is the result. The procedure can be repeated to get a more precise curve fitting.

## Bootstrapping

- \* bootstrap principle:

$\sigma_{\text{(sampling w/replacement)}} = \sigma_{\text{(across samples)}}$

- \* bootstrap iterations:  $B$

\* original sample:  $(x_i, y_i)_{i=1}^N$

\* bootstrap samples:  $(x_{j(b)}, y_{j(b)})_{j \in I}$  for  $b = 1, \dots, B$ ,  $I = \{1, \dots, N\}$ , and  $j$  is the index that is randomly sampled from  $I$

- \* for each  $b$ , compute  $y_{j(b)}$  using LOWESS or any other model

	b	1	2	3	...	B
j						
1		$y_{1(1)}$	$y_{1(2)}$	$y_{1(3)}$	...	$y_{1(B)}$
2		$y_{2(1)}$	$y_{2(2)}$	$y_{2(3)}$	...	$y_{2(B)}$
...		...	...	...	...	...
N		$y_{N(1)}$	$y_{N(2)}$	$y_{N(3)}$	...	$y_{N(B)}$

- \* for each  $j$  row, the standard deviation  $\sigma_j^{boot}$  is

$$\sigma_j^{boot} = \sqrt{\frac{(\bar{y}_j - \bar{\bar{y}}_j)^2}{B - 1}}$$

- \* sort  $\bar{i}(b)$  by value from min to max  $\rightarrow$  get the 5<sup>th</sup> and 95<sup>th</sup> values to get a 90% confidence interval

## Hypothesis Testing

### T-test, one-sample

- \* null hypothesis  $H_o : \mu = \mu_0$
- \* alternative hypothesis  $H_a : \mu \{=, > \text{ or } < \} \mu_0$
- \*  $t$  - *statistic* standardizes the difference between  $\bar{x}$  and  $\mu_0$

$$t = \frac{\bar{x} - \mu_0}{se(\bar{x})}$$

degrees of freedom  $df = n - 1$

- \*  $p$  - *value*: probability that  $\bar{x}$  was obtained by chance given

$\mu_0 = \mu$ .

- \* **algorithm:** read the t-distribution critical values (chart) for the  $p$  - *value* using  $t$  and  $df$

1 if  $(p - \text{value} < \alpha)$  { reject  $H_o$  and accept  $H_a$  }

else { can't reject  $H_o$  }

- \*  $\alpha$  is the predetermined value of significance (usually 0.05)

- \* if ( $t$  is of the 'wrong' sign)  $p - \text{value} = 1 - p - \text{value}_{chart}$

### paired two-sample t-test

each value of one group corresponds to a value in the other group

- \* **algorithm:** subtract the values for each sample to get one set of values and use  $\mu_0$  to perform a one-sample t-test

### unpaired two-sample t-test

the two populations are independent

- \*  $H_o : \mu_1 = \mu_2$

- \*  $H_a : \mu_1 \{=, > \text{ or } < \} \mu_2$

- \*  $t$  - *statistic*

$$t = \frac{\bar{x}_1 - \bar{x}_2}{se(\bar{x}_1, \bar{x}_2)}$$

degrees of freedom  $df = (n_1 - 1) + (n_2 - 1)$

- \* **algorithm:** same as in one-sample t-test

- \* double the  $p$  - *value* for  $H_a : \mu_1 \neq \mu_2$

- \* **Type I error**  $\alpha$ : probability of rejecting a true  $H_o$

- \* **Type II error**  $\beta$ : probability of failing to reject a false  $H_o$

## Notes

- \* the OLS confidence intervals work asymptotically  $\rightarrow$  they assume the number of available observations is infinite, but it assumes normality

- \* in LOWESS,  $n$  is not infinite, but it does not assume any distribution

## Frequentist Inference

- \* assumes the observed data comes from a probability distribution  $F$
- \*  $x = (x_1, \dots, x_n)$  is the data vector (aka. *the sample's values*)
- \*  $X = (X_1, \dots, X_n)$  is the vector of random variables (aka. *a sample, individual draws of  $F$* )
- \* the expectation property  $\theta = E_F(X_i)$  (aka. the true expectation value of any draw  $X_i$ )
- \*  $\hat{\theta}$  is the best estimate of  $\theta$

usually,

$$\hat{\theta} = t(x) \quad t(x) = \bar{x}$$

where  $t(x)$  is the algorithm

- \*  $\hat{\theta}$  is sample specific, is a realization of  $\hat{\Theta} = t(x)$ . Typically,

$$E_F(\hat{\Theta}) = \mu \quad \mu \text{ is the expected value of producing an estimate using } t(x) \text{ when } x \text{ comes from } F$$

- \* **Bias-Variance Trade-Off:** models with lower bias will have higher variance and vice versa.
- \* **Bias:** error from incorrect assumptions to make target function easier to learn (high bias  $\rightarrow$  missing relevant relations or under-fitting)
- \* **Variance:** error from sensitivity to fluctuations in the dataset, or how much the target estimate would differ if different training data was used (high variance  $\rightarrow$  modelling noise or over-fitting)

$$bias = \mu - \theta$$

$$(aka. \text{ expected } - \text{ true values}) \quad var = E_F\{(\hat{\Theta} - \mu)^2\}$$

## Frequentist principles

- \* usually defines parameters with infinite sequence of trials  $\rightarrow$  hypothetical data sets  $X^{(1)}, X^{(2)}, \dots$  generate infinite samples  $\hat{\Theta}^{(1)}, \hat{\Theta}^{(2)}, \dots$
- \* 1) Plug-in principle: relate the sample  $se(\bar{x})$  with the true variance.

$$var_F(x) = var_F = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2$$

$$se(\bar{x}) = \left[ \frac{var_F(x)}{n} \right]^{\frac{1}{2}}$$

- \* 2) Taylor series approximations: relate  $t(x)$  by local linear approximations (aka. compute  $\bar{se}(x)$  of the transformed estimator)

$$se(\hat{\theta}) = se(\bar{x}) \frac{d\hat{\theta}}{d\bar{x}} = se(\bar{x}) \frac{dt(x)}{d\bar{x}}$$

- \* 3.1) Parametric Families: given  $x = (x_1, \dots, x_n)$ , the Likelihood Function  $L(x)$  (aka. the probability to observe  $x$ ) is given by:  
e.g.  $\hat{\theta} = \mu$  for a normal distribution

$$P(x|N(\mu, \sigma^2)) = P(x_1|N(\mu, \sigma^2)) \dots P(x_n|N(\mu, \sigma^2))$$

$$P(x|N(\mu, \sigma^2)) = \left( \frac{1}{\sqrt{2\pi\sigma^2}} \right)^n \prod_{i=1}^n e^{-\frac{(x_i - \mu)^2}{2\sigma^2}} = L(x)$$

$$L(x) = \prod_{i=1}^n f_{\theta}(x_i)$$

- where  $f_{\theta}$  is the density function
- \* 3.2) MLE (maximum likelihood estimate): find  $\hat{\theta}$  such that  $L(x)$  is maximized  
e.g.

$$\max_{\hat{\theta}} L(x) \Rightarrow \max_{\hat{\mu}} L(x) = \hat{\mu}^{MLE}$$

- \* 4) Simulation and Bootstrap: estimate  $F$  as  $\hat{F}$ , then simulate values from  $\hat{F}$  to get a prior sample  $\hat{\Theta}^{(k)} = t(x^{(b)})$   
The empirical standard deviation of the  $\hat{\Theta}'s$  is the frequentist estimate for  $se(\hat{\theta})$
- \* 5) Pivotal Statistics: Frequentist use pivotal statistics whenever they are available to conduct stat. tests  
e.g. t-test is a pivotal statistic as it does not depend on parameters the distribution might have.

## Frequentist Optimality

- Neyman-Pearson lemma optimum hypothesis-testing algorithm:  
purpose: choose one of the two possible density functions for observed data  $x$
- \* null hypothesis density  $f_0(x)$
- \* alternative density  $f_1(x)$
- let  $L(x)$  be the Likelihood Ratio

$$L(X) = \frac{f_1(X)}{f_0(X)}$$

let the testing rule  $t_c x$  be:

$$t_c x = \begin{cases} 1(pic f_1(x)), & \ln(L(X)) \geq c \\ 0(pic f_0(x)), & \ln(L(X)) < c \end{cases}$$

- \* only rules in the  $t_c x$  form can be optimal *problem Steps*
- \* 1) define the density functions  $f_0(x_i)$  and  $f_1(x_i)$  for  $f_0(x)$  and  $f_1(x)$   
e.g.

$$f_0 \sim N(\mu_0, \sigma_0^2)$$

$$f_0 \sim N(0, 1)$$

$$f_0(x_i) = \frac{1}{\sqrt{2\pi}} e^{-\frac{x_i^2}{2}}$$

$$f_1 \sim N(\mu_1, \sigma_1^2)$$

$$f_1 \sim N(0.5, 1)$$

$$f_1(x_i) = \frac{1}{\sqrt{2\pi}} e^{-\frac{x_i - 0.5^2}{2}}$$

- \* 2) calculate the likelihood functions  $f_0(X)$  and  $f_1(X)$   
e.g.

$$f_0(X) = \left[ \frac{1}{\sqrt{2\pi}} \right]^n e^{-\frac{1}{2} \sum_{i=1}^n x_i^2}$$

$$f_1(X) = \left[ \frac{1}{\sqrt{2\pi}} \right]^n e^{-\frac{1}{2} \sum_{i=1}^n ((x_i - 0.5)^2)}$$

- \* 3) calculate the likelihood ratio  
e.g.

$$L(X) = \frac{e^{-\frac{1}{2} \sum_{i=1}^n ((x_i - 0.5)^2)}}{e^{-\frac{1}{2} \sum_{i=1}^n x_i^2}}$$

$$L(X) = e^{-\frac{1}{2} [n\bar{x} - \frac{n}{4}]}$$

- \* 4) remove all independent variables e.g.

$$L(X) > c \Rightarrow \begin{aligned} e^{-\frac{1}{2} [n\bar{x} - \frac{n}{4}]} &> c_1 \\ -\frac{1}{2} \left[ n\bar{x} - \frac{n}{4} \right] &> C_2 \\ n\bar{x} - \frac{n}{4} &> c_3 \\ \bar{x} &> c_4 \\ \bar{x} &> c \end{aligned}$$

- only the mean depends on the sample  $x$
- \* 5) the *most powerful* hypothesis test at any type I error rate  $\alpha$  is to compare  $c$  to a constant.  
e.g.

$$\begin{aligned} \alpha &= P(\bar{x} > c | \mu = \mu_0) \\ \alpha &= P((\bar{x} - \mu)\sqrt{n} > (c - \mu)\sqrt{n} | \mu = 0) \\ \alpha &= 1 - P(\bar{x}\sqrt{n} \leq c\sqrt{n} | \mu = 0) \\ \alpha &= 1 - \Phi(c\sqrt{n}) \end{aligned}$$

- $\Phi$  is the cumulative density function (CDF) of a normal distribution  $N(\mu_0, \sigma_0^2)$
- \* 6) calculate  $c$   
e.g.

In general:

$$\begin{aligned} \Phi(c\sqrt{n}) &= 1 - \alpha \\ c\sqrt{n} &= \Phi^{-1}(1 - \alpha) \\ c &= 0 + \frac{1}{\sqrt{n}} \Phi^{-1}(1 - \alpha) \quad c = \mu_0 + \frac{1}{\sqrt{n}} \Phi^{-1}(1 - \alpha) \end{aligned}$$

- \* 7) calculate  $\beta$ , such that it's minimized  
e.g.

$$\begin{aligned} \beta &= P(\bar{x} \leq c | \mu = \mu_1) \\ \beta &= P((\bar{x} - \mu)\sqrt{n} \leq (c - \mu)\sqrt{n} | \mu = 0.5) \\ \beta &= \Phi((c - 0.5)\sqrt{n}) \end{aligned}$$

## Notes and Details

- \*  $1 - \beta$  is the power of the hypothesis test (probability of correctly rejecting  $f_0(x)$ )

## Bayesian Inference

### Bayes Rule

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)}$$

- \* Bayes Rule (for one  $\mu$ ) can be written as:

$$g(\mu|x) = c_x L_x(\mu) \Pi(\mu)$$

where:  
 $\mu$  : an unobserved point in the parameter space  $\Omega$   
 $x$  : a point in the sample space  $X$   
 $c_x$  : normalization constant of the posterior distribution  
 $g(\mu|x)$  : posterior distribution  
 $L_x(\mu)$  : likelihood function  
 $\Pi(\mu)$  : prior distribution

- \* Bayes Rule (for two  $\mu_1, \mu_2$ ) can be written as:

$$\frac{g(\mu_1|x)}{g(\mu_2|x)} = \frac{g(\mu_1)}{g(\mu_2)} \frac{L_x(\mu_1)}{L_x(\mu_2)}$$

$$L_x(\mu) = \prod_{i=1}^n e^{-\frac{1}{2}(x_i - \mu)^2}$$

### Warm-up example

e.g. Find the probability of identical twins. The doctor says that  $\frac{1}{3}$  of twin births are identical. A sonogram observed same sex. identical twins are of the same sex, while fraternal have 0.5 probability to be of the same sex.

$$\frac{g(\text{identical}|\text{sameSex})}{g(\text{fraternal}|\text{sameSex})} = \frac{g(\text{identical})}{g(\text{fraternal})} \times \frac{L_{\text{identical}}(\text{sameSex})}{L_{\text{fraternal}}(\text{sameSex})}$$

$$\frac{g(\text{identical}|\text{sameSex})}{g(\text{fraternal}|\text{sameSex})} = \frac{\frac{1}{3}}{1 - \frac{1}{3}} \times \frac{1}{\frac{1}{2}}$$

### Flaws in Frequentist Inference

\* In Frequentist, if the algorithm changes (even if the data points stay exactly the same), the significance level is different for each algorithm.

\* On Bayesian inference, the algorithm stays the same  $\rightarrow$  the significance level does not change.

### A Bayesian/Frequentist Comparison List

<b>Bayesian:</b>	<b>Frequentist:</b>
	* attention is in choosing a prior $\Pi$
* attention is in choosing an algorithm $t(x)$	* operates with one parameter (specific question) in many samples
* operates only in one sample with the whole parameter space	* only computes the expected value and the variance (each answer requires an specific algorithm)
* answers all posible questions at once, since the posterior is a distribution	* is more flexible than Bayes as we can come up with many algorithms

### Notes and Details

\* like in frequentist, the fundamental unit of inference is a family of probability densities.

\* Bayesian inferences assumes the knowledge of a prior density  $g(\mu), \mu \in \Omega$

### Fisherian Inference and Maximum Likelihood Estimation

\* The log-likelihood function is defined as:

$$\ell_x(\theta) = \text{Log}\{f_\theta(x)\}$$

for a fixed  $x$  and a variable  $\theta$

$\ell_x(\theta)$  : gets the most likely parameters to get the sample  $x$   
 $f_\theta(x)$  : likelihood function (aka. family probability densities)  $\theta$  : vector of parameters

The posterior odds ratio is the prior odds ratio times the likelihood ratio

\* The MLE is the value of  $\theta \in \Omega$  that maximizes  $\ell_x(\theta)$

$$MLE : \hat{\theta} = \underset{\theta \in \Omega}{\text{argmax}} \{ \ell_x(\theta) \}$$

\* Estimate functions of the true parameter:  $\hat{\gamma} = T(\hat{\theta})$

\* Good frequentist properties (good bias & variance):

$$\text{bias} = \mu - E(\hat{\mu})$$

$$\text{variance} = \sum_{i=1}^I (\hat{\mu}^{(i)} - E(\hat{\mu}))^2$$

$\mu$  : true value of the parameter  
 $E(\hat{\mu})$  : expected value of the estimate

$$\text{variance} = E_F\{(\hat{\mu}^{(i)} - E(\hat{\mu}))^2\}$$

\* Reasonable Bayesian justification

$$P(\theta|x) = c_x \Pi(\theta) e^{\ell_x(\theta)}$$

$P(\theta|x)$  : posterior  
 $c_x$  : constant  
 $\Pi(\theta)$  : prior  
 $e^{\ell_x(\theta)}$  : maximum likelihood estimation

\* Fisherian inference assumes a flat prior (aka. unknown prior), so that the MLE  $\hat{\theta}^{MLE}$  is a maximizer of  $P(\theta|x)$ . (The MLE is the highest point of the posterior distribution)  
 \* As the algorithm does not change, the significance level is not affected by unexpected changes in the algorithm.

e.g. - for a Normal density function

\* let  $\theta = (\mu, \sigma^2)$

\* density function  $f_\theta = \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{1}{2}\left(\frac{x_i - \mu}{\sigma}\right)^2}$  \* Since:

$$L(x) = \prod_{i=1}^n f_\theta(x_i) \text{ Log-Likelihood function}$$

$$\ell_x(\theta) = \sum_{i=1}^n \text{Log}\{f_\theta(x_i)\} = \sum_{i=1}^I \ell_x(\theta)$$

$$\mu^{\hat{MLE}} = \bar{x}$$

$$\sigma^{MLE} = \sqrt{\frac{\sum_{i=1}^n (x_i - \bar{x})^2}{n}}$$

\* MLE can cause over-fitting identification problems when we fit a lot of parameters in  $\theta$  (it would become very specific to our sample  $\rightarrow$  may not represent the population)

### Fisher Information and the MLE

Log-Likelihood Function

$$\ell_x(\theta) = \text{Log} f_\theta(x)$$

Score Function

how higher or lower is the likelihood function value of the sample as  $\theta$  varies?

$$\dot{\ell}_x(\theta) = \frac{\dot{f}_\theta(x)}{f_\theta(x)}$$

Expectation of  $\dot{\ell}_x(\theta)$

$$E(x) = \int_x x f(x) dx$$

$f(x)$  : density function

$$E[\dot{\ell}_x(\theta)] = 0$$

Variance of  $\dot{\ell}_x(\theta)$

$$V[x] = \int_x [x - E(x)]^2 f(x) dx$$

$$V[\dot{\ell}_x(\theta)] = \int_x [\dot{\ell}_x(\theta)]^2 f_\theta(x) dx$$

Fisher Information  $I_0$

$$I_0 = V[\dot{\ell}_x(\theta)]$$

$$\ddot{\ell}_x(\theta) = \frac{\ddot{f}_\theta(x)}{f_\theta(x)} - \left( \frac{\dot{f}_\theta(x)}{f_\theta(x)} \right)^2 \quad E(\ddot{\ell}_x(\theta)) = -I_0$$

MLE estimator of  $\hat{\theta} : \hat{\theta}^{MLE}$

$$\hat{\theta}^{MLE} \sim N\left(\theta, \frac{1}{I_0}\right)$$

e.g. for a normal dist.

let  $x_i \sim N(\theta, \sigma^2)$

\* 1) compute  $\ell_x(\theta)$

$$\text{density function } f_\theta(x) = \prod_{i=1}^n \frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{(x_i - \mu)^2}{2\sigma^2}}$$

$$\text{likelihood function } \ell_x(\theta) = -\frac{1}{2} \sum_{i=1}^n \frac{(x_i - \theta)^2}{\sigma^2} - \frac{n}{2} \text{Log}(2\pi\sigma^2)$$

\* 2) score function  $\dot{\ell}_x(\theta) = \frac{1}{\sigma^2} \sum_{i=1}^n (x_i - \theta)$

$$\ddot{\ell}_x(\theta) = -\frac{n}{\sigma^2}$$

\* 3) compute  $I_0$

as  $E(\ddot{\ell}_x(\theta)) = -I_0$ , Fisher Information  $I_0 = \frac{n}{\sigma^2}$

\* 4) compute  $\hat{\theta}^{MLE}$

$$E(\dot{\ell}_x(\theta)) = \frac{1}{\sigma^2} \sum_{i=1}^n (x_i - \theta) = 0, \text{ such that}$$

$$\sum_{i=1}^n x_i = n\theta \Rightarrow \hat{\theta}^{MLE} = \frac{\sum_{i=1}^n x_i}{n} = \bar{x}$$

\* 5) compute  $se(\hat{\theta}^{MLE})$

for a large n,

$$\hat{\theta}^{MLE} \sim N\left(\theta, \frac{1}{I_0}\right) \Rightarrow \hat{\theta}^{MLE} \sim N\left(\theta, \frac{\sigma^2}{n}\right)$$

$$se(\hat{\theta}^{MLE}) = \frac{1}{I_0} = \frac{\sigma^2}{n}$$

\* 6)  $se(\hat{\theta}^{MLE}) = \frac{1}{nI_0}$ , by Cramer-Rao lower bound.

The MLE has variance at least as small as the best unbiased estimate of  $\theta$

## Conditional Inference

e.g. An *iid* sample  $x \sim N(\theta, 0)$  has produced estimate  $\hat{\theta} = \bar{x}$ . however,

$n = 25$  was declined

$$n = \begin{cases} 25, & \text{prob } \frac{1}{2} \\ 100, & \text{prob } \frac{1}{2} \end{cases}$$

\* Classical Frequentist rational:

$$sd(\bar{x}) = \sigma_{\bar{x}} = \sqrt{\frac{1}{2} \frac{\sigma^2}{100} + \frac{1}{2} \frac{\sigma^2}{25}} = 0.158$$

\* Conditional Inference rational:

$$sd(\bar{x}) = \sqrt{\frac{\sigma^2}{25}} = 0.2$$

\* use the likelihood function (based on observation) without the prior

\* “just take the sample you have”

1) more relevant inferences (w/what really happened)

2) simpler inferences (no correlation between the result and the sample size selection)

e.g. Observed Fisher Information  $I_{(x)}$

$$I_{(x)} = -\ddot{\ell}_x(\hat{\theta}^{MLE})$$

In large samples  $I_{(x)} = I_0$ . Use  $I_{(x)}$  in small samples

$$E[I_{(x)}] = nI_0$$

\* 1) compute the log-likelihood

$$f_{\theta}(x) = \frac{1}{\pi} \frac{1}{1 + (x + \theta)^2} \Rightarrow \text{Cauchy density function}$$

$$\ell_x(\theta) = \text{Log}\left(\frac{1}{\pi}\right) + \text{Log}(1) - \text{Log}(1 + (x + \theta)^2)$$

\* 2) get its derivative

$$\dot{\ell}_x(\theta) = \frac{2(x - \theta)}{1 + (x + \theta)^2}$$

\* 3) get the 2nd derivative

$$\ddot{\ell}_x(\theta) = \frac{-2(1 + (x - \theta)^2) + 4(x - \theta)^2}{(1 + (x - \theta)^2)^2}$$

\* 4) get the observed fisher information

$$I_{(x)} = -\ddot{\ell}_x(\hat{\theta}^{MLE})$$

\* 5) get the variance of the estimate, even if the distribution does not have a defined variance or expected value

- for 10000 samples of size  $n$  with  $\theta = 0$ , compute  $1/I_{(x)}$  and  $\hat{\theta}^{MLE}$

- group the 10000  $\hat{\theta}^{MLE}$  values according to quantiles of  $1/I_{(x)}$  and calculate the empirical variance for each sample.

\* for all samples, the unconditional variance  $1/nI_0$  is the same because all the samples are of the same size.

\* on the other hand,  $I_{(x)}$  will vary from sample to sample ( $\hat{\theta}^{MLE}$  is different for each sample). \*  $I_{(x)}$  is related to the variance.

## Permutation and Randomization

\* when performing a t-test, it's assumed that the data samples come from a normal distribution.

\* small samples may follow a different distribution.

Randomization removes the normality assumption

\* Randomization is: taking random groups from the data that are of the same size as the tested groups.

\* 1) compute the t-statistic for each randomly sampled pair of groups

\* 2) get the t-statistic histogram

Utilizing random generated groups, it's expected the t-values not to be very high  $\rightarrow$  construct an empirical distribution of t-values

## Parametric Models and Exponential Families

### Univariate Families

Name Notation	Density	X	$\Omega$	E Var
Normal $N(\mu, \sigma^2)$	$\frac{1}{\sqrt{2\pi\sigma^2}} e^{-\frac{1}{2} \frac{(x-\mu)^2}{\sigma^2}}$	$\mathbb{R}^{(1)}$	$\mu \in \mathbb{R}^{(1)}$ $\sigma^2 \in \mathbb{R}^+$	$\mu$ $\sigma^2$

\* has two parameters, but they are very specific.  $\mu$  is the location parameter, and  $\sigma^2$  is the wide/narrow parameter

\* model quantities that take positive and/or negative continuous values, if the distribution is symmetric and if there are not too many extreme values

Name Notation	Density	X	$\Omega$	E Var
Poisson $Poi(\lambda)$	$\frac{e^{-\lambda} \lambda^x}{x!}$	$\mathbb{N}_0$	$\lambda \in \mathbb{R}^+$	$\lambda$ $\lambda$

\* if the mean grows/shrinks the variance also grows/shrinks proportionally

\*  $\lambda$  must stay positive and is the interval of time of an exponential distribution, which is continuous  $\rightarrow$  the expected number of successes can have decimals

\* model a quantity that is discrete, it's the number of counts of something

\* It's not very flexible as only has one parameter to tweak

Name Notation	Density	X	$\Omega$	E Var
Binomial $Bi(n, \theta)$	$\binom{n}{x} \theta^n (1 - \theta)^{n-x}$	$\{0, \dots, n\}$	$0 \leq \theta \leq 1$	$n\theta$ $n\theta(1 - \theta)$

\* model the count of successes as Poisson, but we know the number of trials  $n$

Name Notation	Density	X	$\Omega$	E Var
Gamma $Ga(\nu, \sigma)$	$\frac{x^{\nu-1} e^{-\frac{x}{\sigma}}}{\sigma^{\nu} \Gamma(\nu)}$	$\mathbb{R}^+$	$\nu > 0$ $\sigma > 0$	$\sigma\nu$ $\sigma^2\nu$

\* the Gamma is used to model positive quantities. its common to use the inverse Gamma to model variances.

Name Notation	Density	X	$\Omega$	E Var
Beta $Be(\alpha, \beta)$	$\frac{x^{\alpha-1} (1-x)^{\beta-1}}{B(\alpha, \beta)}$	$0 \leq x \leq 1$	$\alpha > 0$ $\beta > 0$	$\frac{\alpha}{\alpha+\beta}$ $\frac{\alpha}{\alpha+\beta} \frac{\beta}{\alpha+\beta}$

$$var = \frac{\alpha\beta}{(\alpha+\beta)^2(\alpha+\beta+1)}$$

\* as  $x$  goes from 0 to 1, it's mostly used to talk about probabilities (aka. probability distribution)

\* both the Gamma and Beta have two parameters that convey some degree of flexibility

\* Gamma is flexible but not as flexible as Beta

\* The Binomial can approximate a Poisson with a large  $n$  and small probability.
